Class 11 Chemistry Chapter 7 – Notes and Extra Questions

Redox Reactions is the first chapter of Part 2 of the NCERT Class 11 Chemistry textbook (2026-27 rationalised edition), and it builds the electron-transfer and oxidation-number toolkit that students will reuse throughout electrochemistry, p-block chemistry, and inorganic qualitative analysis in Class 12. The chapter moves from the classical idea of oxidation and reduction, through oxidation number rules and the two methods of balancing redox equations (oxidation-number method and ion-electron/half-reaction method), to redox reactions as electrode processes governed by standard electrode potentials. Below you will find fully worked, independently re-derived solutions to every question in the current NCERT Exercise for Chapter 7, covering oxidation-number assignment, disproportionation, redox balancing, and electrochemical-cell/electrode-potential problems.

## NCERT Solutions for Class 11 Chemistry Chapter 7: Redox Reactions

### Q7.1: Assign oxidation numbers to the underlined elements

**Assign oxidation numbers to the underlined element in each of the following species:**

- (a)  $\text{NaH}_2\text{PO}_4$  (P):  $\text{Na} = +1$ , each  $\text{O} = -2$ . Let  $\text{P} = x$ .  $1 + 2(1) + x + 4(-2) = 0 \rightarrow 1 + 2 + x - 8 = 0 \rightarrow x = +5$ .  
(b)  $\text{NaHSO}_4$  (S):  $1 + 1 + x - 8 = 0 \rightarrow x = +6$ .  
(c)  $\text{H}_4\text{P}_2\text{O}_7$  (P):  $4(+1) + 2x + 7(-2) = 0 \rightarrow 4 + 2x - 14 = 0 \rightarrow 2x = 10 \rightarrow x = +5$  per P atom.  
(d)  $\text{K}_2\text{MnO}_4$  (Mn):  $2(+1) + x + 4(-2) = 0 \rightarrow 2 + x - 8 = 0 \rightarrow x = +6$ .  
(e)  $\text{CaO}_2$  (O, calcium peroxide): Ca is always +2, and  $\text{CaO}_2$  contains a peroxide (O-O) linkage, so each O = -1 (not -2). Check:  $+2 + 2(-1) = 0$ .  $\rightarrow \text{O} = -1$ .  
(f)  $\text{NaBH}_4$  (B): H is bonded to a less electronegative element (B), so H = -1 (hydridic hydrogen).  $1 + x + 4(-1) = 0 \rightarrow 1 + x - 4 = 0 \rightarrow x = +3$ .  
(g)  $\text{H}_2\text{S}_2\text{O}_7$  (S, pyrosulphuric acid/oleum):  $2(+1) + 2x + 7(-2) = 0 \rightarrow 2 + 2x - 14 = 0 \rightarrow 2x = 12 \rightarrow x = +6$  per S atom.  
(h)  $\text{KAl}(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$  (S, potash alum): each  $\text{SO}_4^{2-}$  group has  $\text{O} = -2 \times 4 = -8$ , so  $\text{S} + (-8) = -2 \rightarrow \text{S} = +6$ .

**Final answer: P = +5, S = +6, P = +5, Mn = +6, O = -1, B = +3, S = +6, S = +6 respectively (worked from first principles above).**

### Q7.2: Oxidation numbers that need structural rationalisation

**What are the oxidation numbers of the underlined elements in the following, and how do you rationalise your results?**

- (a)  $\text{KI}_3$ : In  $\text{KI}_3$ , the  $\text{I}_3^-$  ion is not three equivalent iodine atoms — it is an  $\text{I}_2$  molecule (both atoms at oxidation state 0) coordinated to an  $\text{I}^-$  ion (oxidation state -1). The formula-based “average” calculation gives  $-1/3$  per I atom [ $\text{K} = +1$ , so  $3(\text{I}) = -1$ , average  $\text{I} = -1/3$ ], but this average has no physical meaning; the true picture is two I atoms at 0 and one I atom at -1.  
(b)  $\text{H}_2\text{S}_4\text{O}_6$  (tetrathionate): Average from the formula:  $2(+1) + 4x + 6(-2) = 0 \rightarrow 2 + 4x - 12 = 0 \rightarrow x = +2.5$ . Structurally, tetrathionate has a chain  $\text{O}_3\text{S}-\text{S}-\text{S}-\text{SO}_3$ : the two central sulphur atoms (bonded only to other S atoms) are at 0, and the two terminal ( $\text{SO}_3$ -type) sulphur atoms are at +5 each. Average =  $(0+0+5+5)/4 = +2.5$  — matches the formula average, but the real oxidation states are 0, 0, +5, +5, not four identical +2.5 atoms.  
(c)  $\text{Fe}_3\text{O}_4$  (magnetite): Formula average:  $3x + 4(-2) = 0 \rightarrow x = +8/3$ . Structurally  $\text{Fe}_3\text{O}_4$  is  $\text{FeO} \cdot \text{Fe}_2\text{O}_3$ , i.e., one  $\text{Fe}^{2+}$  and two  $\text{Fe}^{3+}$ ; average =  $(2+3+3)/3 = +8/3$ , confirming the mix of +2 and +3 iron.  
(d)  $\text{CH}_3\text{CH}_2\text{OH}$  (ethanol): Formula average:  $2x + 6(+1) + 1(-2) = 0 \rightarrow 2x = -4 \rightarrow x = -2$  per C. By bond-by-

bond counting (C-H gives C = -1, C-O gives C = +1, C-C gives 0): the methyl carbon (3 C-H, 1 C-C) = -3; the CH<sub>2</sub>OH carbon (2 C-H, 1 C-O, 1 C-C) = -1. Average = (-3 + -1)/2 = -2, matching the formula value, but the two carbons individually are -3 and -1, not both -2.

(e) CH<sub>3</sub>COOH (acetic acid): Formula average:  $2x + 4(+1) + 2(-2) = 0 \rightarrow 2x = 0 \rightarrow x = 0$  per C. By structure: the methyl carbon = -3 (3 C-H bonds); the carboxyl carbon (one C=O counted as two O-bonds, one C-OH, one C-C) = +2 + 1 + 0 = +3. Average = (-3 + 3)/2 = 0, matching the formula, but individually the carbons are -3 and +3, not both 0.

**Final answer: The formula-based averages (-1/3, +2.5, +8/3, -2, 0) are mathematically correct but physically misleading, since each of these species contains chemically non-equivalent atoms of the same element at different real oxidation states, as shown above.**

### Q7.3: Justify that these reactions are redox reactions

---

**Justify that the following reactions are redox reactions:**

(a)  $\text{CuO(s)} + \text{H}_2\text{(g)} \rightarrow \text{Cu(s)} + \text{H}_2\text{O(g)}$ : Cu goes from +2 (in CuO) to 0 (reduction); H goes from 0 (in H<sub>2</sub>) to +1 (in H<sub>2</sub>O) (oxidation). Both oxidation and reduction occur, so it is a redox reaction.

(b)  $\text{Fe}_2\text{O}_3\text{(s)} + 3\text{CO(g)} \rightarrow 2\text{Fe(s)} + 3\text{CO}_2\text{(g)}$ : Fe goes from +3 to 0 (reduction); C goes from +2 (in CO) to +4 (in CO<sub>2</sub>) (oxidation). Redox reaction.

(c)  $4\text{BCl}_3\text{(g)} + 3\text{LiAlH}_4\text{(s)} \rightarrow 2\text{B}_2\text{H}_6\text{(g)} + 3\text{LiCl(s)} + 3\text{AlCl}_3\text{(s)}$ : assigning carefully, in B<sub>2</sub>H<sub>6</sub>, H is bonded to less electronegative B, so H = -1 and B = +3 (since  $2\text{B} + 6(-1) = 0 \rightarrow \text{B} = +3$ , unchanged from BCl<sub>3</sub>). The actual electron transfer is on hydrogen: H in LiAlH<sub>4</sub> is -1 (hydridic), and H in B<sub>2</sub>H<sub>6</sub> is also -1, so hydrogen is transferred as a hydride ion without a net oxidation-state change either. This is essentially a metathesis (double-displacement) reaction with no change in oxidation number for any atom, so despite appearances it is *not* a genuine electron-transfer redox reaction — it proceeds by hydride-ion transfer, not electron transfer between different oxidation states.

(d)  $2\text{K(s)} + \text{F}_2\text{(g)} \rightarrow 2\text{K}^+\text{F}^-\text{(s)}$ : K goes from 0 to +1 (oxidation); F goes from 0 to -1 (reduction). Redox reaction.

(e)  $4\text{NH}_3\text{(g)} + 5\text{O}_2\text{(g)} \rightarrow 4\text{NO(g)} + 6\text{H}_2\text{O(g)}$ : N goes from -3 (in NH<sub>3</sub>) to +2 (in NO) (oxidation); O goes from 0 to -2 (reduction). Redox reaction.

**Final answer: Reactions (a), (b), (d) and (e) are genuine redox reactions with a clear change in oxidation number of at least two elements; reaction (c) shows no net oxidation-state change on careful analysis and is better classified as a hydride-transfer metathesis reaction, a subtlety many secondary sources skip over.**

### Q7.4: Is the reaction of fluorine with ice a redox reaction?

---

Fluorine reacts with ice:  $\text{H}_2\text{O(s)} + \text{F}_2\text{(g)} \rightarrow \text{HF(g)} + \text{HOF(g)}$ . Assign oxidation numbers: in H<sub>2</sub>O, H = +1, O = -2. In F<sub>2</sub>, F = 0. In HF, H = +1, F = -1. In HOF (hypofluorous acid), fluorine (more electronegative than O) takes -1 as usual, and since  $\text{H}(+1) + \text{O}(x) + \text{F}(-1) = 0$  for the neutral molecule, oxygen must be assigned 0 here (pushed toward a less negative state because it is bonded to the more electronegative F). So oxygen's oxidation number changes from -2 (in H<sub>2</sub>O) to 0 (in HOF) — an oxidation — while fluorine goes from 0 (in F<sub>2</sub>) to -1 (in both HF and HOF) — a reduction.

**Final answer: Yes, it is a redox reaction: oxygen is oxidised from -2 to 0, and fluorine is reduced from 0 to -1.**

### Q7.5: Oxidation numbers of S, Cr and N — and the “fallacy”

Calculate the oxidation number of sulphur, chromium and nitrogen in  $\text{H}_2\text{SO}_5$ ,  $\text{Cr}_2\text{O}_7^{2-}$  and  $\text{NO}_3^-$ . Suggest the structures of these compounds and account for the fallacy.

**$\text{H}_2\text{SO}_5$  (peroxomonosulphuric acid / Caro's acid):** A naive calculation treating all five oxygens as -2 gives  $2(+1) + x + 5(-2) = 0 \rightarrow x = +8$ , which is chemically impossible since sulphur (Group 16) cannot exceed +6. This is the “fallacy.” The correct structure is  $\text{HO-SO}_2\text{-O-O-H}$ : two oxygens are normal double-bonded oxo oxygens (-2 each), one oxygen is a normal -OH oxygen (-2), and two oxygens form a peroxide (-O-O-) linkage (-1 each, as in  $\text{H}_2\text{O}_2$ ). Recomputing:  $x + 2(+1 \text{ for the 2 H}) + 2(-2) + 1(-2) + 2(-1) = 0 \rightarrow x + 2 - 4 - 2 - 2 = 0 \rightarrow x = +6$ .

**$\text{Cr}_2\text{O}_7^{2-}$  (dichromate):**  $2x + 7(-2) = -2 \rightarrow 2x = 12 \rightarrow x = +6$  per Cr. No peroxide linkage is present here, so this is a genuine, unproblematic +6 (the well-known Cr(VI) state).

**$\text{NO}_3^-$  (nitrate):**  $x + 3(-2) = -1 \rightarrow x = +5$ . This is nitrogen's maximum possible oxidation state (Group 15) and is likewise unproblematic.

**Final answer:** S in  $\text{H}_2\text{SO}_5$  = +6 (not the naive +8, corrected for the O-O peroxide linkage), Cr in  $\text{Cr}_2\text{O}_7^{2-}$  = +6, N in  $\text{NO}_3^-$  = +5. The “fallacy” is applying a blanket -2 to every oxygen even when a peroxide bond is present; only  $\text{H}_2\text{SO}_5$  needed this correction.

### Q7.6: Write formulae for the following compounds

- (a) Mercury(II) chloride:  $\text{HgCl}_2$
- (b) Nickel(II) sulphate:  $\text{NiSO}_4$
- (c) Tin(IV) oxide:  $\text{SnO}_2$
- (d) Thallium(I) sulphate:  $\text{Tl}_2\text{SO}_4$
- (e) Iron(III) sulphate:  $\text{Fe}_2(\text{SO}_4)_3$
- (f) Chromium(III) oxide:  $\text{Cr}_2\text{O}_3$

**Final answer:**  $\text{HgCl}_2$ ,  $\text{NiSO}_4$ ,  $\text{SnO}_2$ ,  $\text{Tl}_2\text{SO}_4$ ,  $\text{Fe}_2(\text{SO}_4)_3$  and  $\text{Cr}_2\text{O}_3$ , obtained by balancing each metal's stated Roman-numeral charge against the standard charge of the anion ( $\text{Cl}^- = -1$ ,  $\text{SO}_4^{2-} = -2$ ,  $\text{O}^{2-} = -2$ ).

### Q7.7: Substances showing carbon (-4 to +4) and nitrogen (-3 to +5) oxidation states

Carbon shows every integral oxidation state from -4 to +4 through:  $\text{CH}_4$  (-4),  $\text{C}_2\text{H}_2$  (-1),  $\text{H}_2\text{C}=\text{CH}_2$  (-2),  $\text{CH}_3\text{OH}$  (-2),  $\text{HCHO}$  (0),  $\text{HCOOH}$  (+2),  $\text{CO}_2$  (+4),  $\text{CCl}_4$  (+4). Nitrogen shows every integral state from -3 to +5 through:  $\text{NH}_3$  (-3),  $\text{N}_2\text{H}_4$  (-2),  $\text{NH}_2\text{OH}$  (-1),  $\text{N}_2$  (0),  $\text{N}_2\text{O}$  (+1),  $\text{NO}$  (+2),  $\text{N}_2\text{O}_3/\text{HNO}_2$  (+3),  $\text{NO}_2$  (+4),  $\text{N}_2\text{O}_5/\text{HNO}_3$  (+5).

**Final answer:** Carbon spans -4 ( $\text{CH}_4$ ) to +4 ( $\text{CO}_2$ ,  $\text{CCl}_4$ ) through intermediate compounds like  $\text{C}_2\text{H}_2$ ,  $\text{CH}_3\text{OH}$ ,  $\text{HCHO}$  and  $\text{HCOOH}$ ; nitrogen spans -3 ( $\text{NH}_3$ ) to +5 ( $\text{HNO}_3$ ) through  $\text{N}_2\text{H}_4$ ,  $\text{NH}_2\text{OH}$ ,  $\text{N}_2$ ,  $\text{N}_2\text{O}$ ,  $\text{NO}$ ,  $\text{HNO}_2$  and  $\text{NO}_2$ , as listed above.

### Q7.8: Why are $\text{SO}_2$ and $\text{H}_2\text{O}_2$ both oxidants and reductants, while $\text{O}_3$ and $\text{HNO}_3$ are only oxidants?

Sulphur in  $\text{SO}_2$  is at +4, an intermediate oxidation state for sulphur (whose range is -2 to +6) — it can rise to +6 (acting as a reducing agent, e.g. being oxidised to  $\text{SO}_4^{2-}$ ) or fall to lower states such as 0 or -2

(acting as an oxidising agent). Similarly, oxygen in  $\text{H}_2\text{O}_2$  is at -1, intermediate between 0 (in  $\text{O}_2$ ) and -2 (in  $\text{H}_2\text{O}$ ), so  $\text{H}_2\text{O}_2$  can be oxidised to  $\text{O}_2$  (acting as reductant) or reduced to  $\text{H}_2\text{O}$  (acting as oxidant). In contrast, in  $\text{O}_3$  the “active” oxygen has no easy access to a still-higher positive oxygen state, and in  $\text{HNO}_3$  nitrogen is at +5, its maximum possible oxidation state — it can only decrease (never increase), so  $\text{HNO}_3$  can only act as an oxidising agent, never as a reducing agent.

**Final answer:**  $\text{SO}_2$  (S = +4) and  $\text{H}_2\text{O}_2$  (O = -1) sit at intermediate oxidation states and can move either up or down, giving them dual oxidising/reducing character, whereas  $\text{O}_3$  and  $\text{HNO}_3$  (N at its ceiling of +5) can only be reduced further, so they act solely as oxidants.

#### Q7.9: Why write the water-balanced form of these reactions, and how to trace the mechanism

---

(a)  $6\text{CO}_2(\text{g}) + 6\text{H}_2\text{O}(\text{l}) \rightarrow \text{C}_6\text{H}_{12}\text{O}_6(\text{aq}) + 6\text{O}_2(\text{g})$  is more correctly written as  $6\text{CO}_2(\text{g}) + 12\text{H}_2\text{O}(\text{l}) \rightarrow \text{C}_6\text{H}_{12}\text{O}_6(\text{aq}) + 6\text{H}_2\text{O}(\text{l}) + 6\text{O}_2(\text{g})$  because, mechanistically, the oxygen gas evolved in photosynthesis comes entirely from water molecules (not from  $\text{CO}_2$ ), so 12 whole water molecules must be shown as reactants to supply the 12 oxygen atoms needed to form 6  $\text{O}_2$ , with 6 water molecules regenerated as products.

(b) Similarly,  $\text{O}_3(\text{g}) + \text{H}_2\text{O}_2(\text{l}) \rightarrow \text{H}_2\text{O}(\text{l}) + 2\text{O}_2(\text{g})$  is better written as  $\text{O}_3(\text{g}) + \text{H}_2\text{O}_2(\text{l}) \rightarrow \text{H}_2\text{O}(\text{l}) + \text{O}_2(\text{g}) + \text{O}_2(\text{g})$ , keeping the two product  $\text{O}_2$  molecules distinct because they originate from two different sources: one  $\text{O}_2$  forms from the peroxide oxygens of  $\text{H}_2\text{O}_2$ , and the other forms from ozone.

The technique used to establish which atoms end up where is **isotopic (heavy-isotope) labelling** — e.g., using water enriched with the oxygen-18 isotope ( $\text{H}_2^{18}\text{O}$ ) and tracking whether the  $^{18}\text{O}$  ends up in the  $\text{O}_2$  product or remains as  $\text{H}_2\text{O}$ , thereby tracing the actual reaction path/mechanism.

**Final answer:** Both equations are rewritten to reflect that all the product  $\text{O}_2$  in each case is mechanistically traceable to specific reactant oxygen atoms (water in photosynthesis;  $\text{H}_2\text{O}_2$  and  $\text{O}_3$  separately in the second case), a fact established using isotopic ( $^{18}\text{O}$ ) tracer studies.

#### Q7.10: Why is $\text{AgF}_2$ a very strong oxidising agent?

---

In  $\text{AgF}_2$ , silver is forced into the unusual +2 oxidation state ( $\text{Ag}^{2+}$ ). This state is highly unstable for silver, because silver’s normal, far more stable oxidation state is +1 ( $\text{Ag}^+$ , with a stable filled d10 configuration).  $\text{Ag}^{2+}$  therefore has a very strong tendency to gain one electron and revert to the stable  $\text{Ag}^+$  state, i.e., to get reduced. A species with such a strong drive to be reduced is, by definition, a powerful oxidising agent.

**Final answer:**  $\text{AgF}_2$  contains silver in the unstable +2 state, which readily gains an electron to fall back to the far more stable +1 state; this strong drive toward reduction makes  $\text{AgF}_2$  (where formed) a very strong oxidising agent.

#### Q7.11: Excess reductant vs. excess oxidant — three illustrations

---

When a redox reaction is carried out with the reducing agent in excess, the product tends to be the one with the lower oxidation state of the variable element; when the oxidising agent is in excess, the product has the higher oxidation state.

- (i) Sulphur with limited  $\text{O}_2$  gives  $\text{SO}_2$  (S = +4); with excess  $\text{O}_2$ /further oxidation,  $\text{SO}_3$  (S = +6) is favoured.
- (ii) Phosphorus with limited  $\text{Cl}_2$  gives  $\text{PCl}_3$  (P = +3); with excess  $\text{Cl}_2$ ,  $\text{PCl}_5$  (P = +5) is formed.

(iii) Copper reacting with dilute  $\text{HNO}_3$  (a comparatively weaker oxidant) gives  $\text{NO}$  ( $\text{N} = +2$ ); with concentrated  $\text{HNO}_3$  (stronger oxidising conditions),  $\text{NO}_2$  ( $\text{N} = +4$ ) is the major product — illustrating the same principle for the oxidant's own reduction product.

**Final answer: Excess reductant → lower oxidation state product (e.g.,  $\text{PCl}_3$ ,  $\text{SO}_2$ ,  $\text{NO}$ ); excess oxidant → higher oxidation state product (e.g.,  $\text{PCl}_5$ ,  $\text{SO}_3$ ,  $\text{NO}_2$ ), as shown in the three illustrations above.**

### Q7.12: Alkaline $\text{KMnO}_4$ for benzoic acid; $\text{HCl}$ gas vs $\text{Br}_2$ vapour with conc. $\text{H}_2\text{SO}_4$

(a) Toluene is oxidised to benzoic acid using alkaline  $\text{KMnO}_4$  (followed by acidification) because the strongly oxidising, alkaline permanganate medium is powerful enough to oxidise the benzylic  $-\text{CH}_3$  side chain all the way to  $-\text{COOH}$  (via the intermediate potassium benzoate) without over-oxidising or degrading the aromatic ring. Balanced equation:

(Atom check: C 7=7, H 8=8, O 8=8, K 2=2, Mn 2=2 — balanced.) The potassium benzoate formed is then acidified to yield free benzoic acid.

(b) When concentrated  $\text{H}_2\text{SO}_4$  is added to a chloride salt, colourless  $\text{HCl}$  gas is evolved because  $\text{Cl}^-$  is too weak a reducing agent to be oxidised by  $\text{H}_2\text{SO}_4$ , so only a simple (non-redox) acid-displacement occurs. But with a bromide salt,  $\text{Br}^-$  is a stronger reducing agent than  $\text{Cl}^-$ , so concentrated  $\text{H}_2\text{SO}_4$  can additionally oxidise the  $\text{HBr}$  formed to red-brown  $\text{Br}_2$  vapour ( $\text{H}_2\text{SO}_4$  itself being reduced, typically to  $\text{SO}_2$ ):  $2\text{HBr} + \text{H}_2\text{SO}_4 \rightarrow \text{Br}_2 + \text{SO}_2 + 2\text{H}_2\text{O}$ .

**Final answer: (a) Alkaline  $\text{KMnO}_4$  fully oxidises the  $-\text{CH}_3$  group to  $-\text{COOK}$  without destroying the ring, per the balanced equation above. (b) Chloride only undergoes acid displacement ( $\text{HCl}$  gas) because  $\text{Cl}^-$  resists oxidation, while bromide's stronger reducing character lets conc.  $\text{H}_2\text{SO}_4$  additionally oxidise  $\text{HBr}$  to  $\text{Br}_2$  vapour.**

### Q7.13: Identify substance oxidised/reduced and oxidising/reducing agents

(a)  $2\text{AgBr}(\text{s}) + \text{C}_6\text{H}_6\text{O}_2(\text{aq}) \rightarrow 2\text{Ag}(\text{s}) + 2\text{HBr}(\text{aq}) + \text{C}_6\text{H}_4\text{O}_2(\text{aq})$ :  $\text{Ag}^+$  (in  $\text{AgBr}$ ) is reduced to  $\text{Ag}(0)$ ; hydroquinone ( $\text{C}_6\text{H}_6\text{O}_2$ ) is oxidised to quinone ( $\text{C}_6\text{H}_4\text{O}_2$ ). Oxidising agent =  $\text{AgBr}$ ; reducing agent = hydroquinone.

(b)  $\text{HCHO}(\text{l}) + 2[\text{Ag}(\text{NH}_3)_2]^+(\text{aq}) + 3\text{OH}^-(\text{aq}) \rightarrow 2\text{Ag}(\text{s}) + \text{HCOO}^-(\text{aq}) + 4\text{NH}_3(\text{aq}) + 2\text{H}_2\text{O}(\text{l})$ :  $\text{HCHO}$  is oxidised to  $\text{HCOO}^-$ ;  $\text{Ag}^+$  (as the diammine complex) is reduced to  $\text{Ag}(0)$ . Oxidising agent =  $[\text{Ag}(\text{NH}_3)_2]^+$ ; reducing agent =  $\text{HCHO}$ .

(c)  $\text{HCHO}(\text{l}) + 2\text{Cu}^{2+}(\text{aq}) + 5\text{OH}^-(\text{aq}) \rightarrow \text{Cu}_2\text{O}(\text{s}) + \text{HCOO}^-(\text{aq}) + 3\text{H}_2\text{O}(\text{l})$ :  $\text{HCHO}$  is oxidised to  $\text{HCOO}^-$ ;  $\text{Cu}^{2+}$  is reduced to  $\text{Cu}^+$  (in  $\text{Cu}_2\text{O}$ ). Oxidising agent =  $\text{Cu}^{2+}$ ; reducing agent =  $\text{HCHO}$ .

(d)  $\text{N}_2\text{H}_4(\text{l}) + 2\text{H}_2\text{O}_2(\text{l}) \rightarrow \text{N}_2(\text{g}) + 4\text{H}_2\text{O}(\text{l})$ :  $\text{N}$  ( $-2$  in  $\text{N}_2\text{H}_4$ ) is oxidised to  $\text{N}_2$  ( $0$ );  $\text{O}$  ( $-1$  in  $\text{H}_2\text{O}_2$ ) is reduced to  $-2$  (in  $\text{H}_2\text{O}$ ). Oxidising agent =  $\text{H}_2\text{O}_2$ ; reducing agent =  $\text{N}_2\text{H}_4$ .

(e)  $\text{Pb}(\text{s}) + \text{PbO}_2(\text{s}) + 2\text{H}_2\text{SO}_4(\text{aq}) \rightarrow 2\text{PbSO}_4(\text{s}) + 2\text{H}_2\text{O}(\text{l})$ :  $\text{Pb}(0)$  is oxidised to  $\text{Pb}^{2+}$  (in  $\text{PbSO}_4$ );  $\text{Pb}$  ( $+4$ , in  $\text{PbO}_2$ ) is reduced to  $\text{Pb}^{2+}$ . Oxidising agent =  $\text{PbO}_2$ ; reducing agent =  $\text{Pb}(\text{s})$ . (This is the discharge reaction of the lead storage battery.)

**Final answer: Oxidising/reducing agent pairs are (a)  $\text{AgBr}$  / hydroquinone, (b)  $[\text{Ag}(\text{NH}_3)_2]^+$  /  $\text{HCHO}$ , (c)  $\text{Cu}^{2+}$  /  $\text{HCHO}$ , (d)  $\text{H}_2\text{O}_2$  /  $\text{N}_2\text{H}_4$ , (e)  $\text{PbO}_2$  /  $\text{Pb}$ , as identified from the oxidation-number changes above.**

### Q7.14: Why does thiosulphate react differently with iodine and bromine?

$2\text{S}_2\text{O}_3^{2-}(\text{aq}) + \text{I}_2(\text{s}) \rightarrow \text{S}_4\text{O}_6^{2-}(\text{aq}) + 2\text{I}^-(\text{aq})$  and  $\text{S}_2\text{O}_3^{2-}(\text{aq}) + 4\text{Br}_2(\text{l}) + 5\text{H}_2\text{O}(\text{l}) \rightarrow 2\text{SO}_4^{2-}(\text{aq}) + 8\text{Br}^-(\text{aq}) + 10\text{H}^+(\text{aq})$ . In thiosulphate, S is at an average +2. Iodine ( $\text{I}_2/\text{I}^-$ ,  $E^\circ = +0.54 \text{ V}$ ) is a comparatively mild oxidising agent, so it can only partially oxidise thiosulphate, taking sulphur from +2 to +2.5 (tetrathionate,  $\text{S}_4\text{O}_6^{2-}$ ). Bromine ( $\text{Br}_2/\text{Br}^-$ ,  $E^\circ = +1.09 \text{ V}$ ) is a much stronger oxidising agent, so it can fully oxidise sulphur all the way to +6 (sulphate,  $\text{SO}_4^{2-}$ ).

**Final answer:** Iodine, being a weaker oxidant, converts thiosulphate only to tetrathionate (S: +2 → +2.5), while the much stronger oxidant bromine drives the oxidation all the way to sulphate (S: +2 → +6).

### Q7.15: Fluorine as best oxidant; hydroiodic acid as best reductant

Among the halogens, fluorine has the highest standard reduction potential ( $\text{F}_2/\text{F}^-$ ,  $E^\circ = +2.87 \text{ V}$ ) due to its small atomic size, very high electronegativity, weak F-F bond, and very high hydration enthalpy of  $\text{F}^-$ , all of which favour  $\text{F}_2$  readily accepting electrons — e.g.,  $\text{F}_2$  oxidises even water:  $2\text{F}_2 + 2\text{H}_2\text{O} \rightarrow 4\text{HF} + \text{O}_2$ , something no other halogen does. Among the hydrohalic acids, HI is the best reductant because the H-I bond is the weakest (largest, most polarisable iodine atom, longest and weakest bond), so  $\text{I}^-$  is oxidised most easily of all the halide ions — e.g., HI reduces concentrated  $\text{H}_2\text{SO}_4$  all the way to  $\text{H}_2\text{S}$ , whereas HCl cannot reduce  $\text{H}_2\text{SO}_4$  at all.

**Final answer:**  $\text{F}_2$  is the best oxidant due to its high electronegativity, small size, weak F-F bond and high hydration energy of  $\text{F}^-$  (highest  $E^\circ$ ); HI is the best reductant because its weak H-I bond lets  $\text{I}^-$  lose an electron most readily of all the halides.

### Q7.16: $\text{XeO}_6^{4-}$ reacting with fluoride — what it reveals about $\text{Na}_4\text{XeO}_6$

$\text{XeO}_6^{4-}(\text{aq}) + 2\text{F}^-(\text{aq}) + 6\text{H}^+(\text{aq}) \rightarrow \text{XeO}_3(\text{g}) + \text{F}_2(\text{g}) + 3\text{H}_2\text{O}(\text{l})$ . Xenon falls from +8 (in the perxenate ion,  $\text{XeO}_6^{4-}$ ) to +6 (in  $\text{XeO}_3$ ) — a reduction — while fluoride is oxidised from -1 to 0 ( $\text{F}_2$ ). Since  $\text{F}_2/\text{F}^-$  already has the highest known standard reduction potential of any common couple (+2.87 V), for perxenate to be able to oxidise  $\text{F}^-$  to  $\text{F}_2$  at all, the  $\text{XeO}_6^{4-}/\text{XeO}_3$  couple must have an even higher reduction potential than  $\text{F}_2/\text{F}^-$ .

**Final answer:** The reaction shows that perxenate (as in  $\text{Na}_4\text{XeO}_6$ ) is an exceptionally powerful oxidising agent — stronger even than elemental fluorine — since it is able to oxidise  $\text{F}^-$  ions to  $\text{F}_2$  gas.

### Q7.17: What $\text{Ag}^+$ vs $\text{Cu}^{2+}$ reactions reveal about their oxidising strength

$\text{H}_3\text{PO}_2$  reduces both  $[\text{Ag}(\text{NH}_3)_2]^+$  and  $\text{Cu}^{2+}$  to the metal/lower oxide. Benzaldehyde ( $\text{C}_6\text{H}_5\text{CHO}$ , an aromatic aldehyde) reduces  $[\text{Ag}(\text{NH}_3)_2]^+$  (Tollens' reagent) to metallic silver, but shows no reaction at all with  $\text{Cu}^{2+}$  (Fehling-type reagent). This shows that  $\text{Ag}^+$  is a distinctly stronger oxidising agent than  $\text{Cu}^{2+}$  — strong enough to oxidise even a comparatively resistant aromatic aldehyde, which  $\text{Cu}^{2+}$  cannot do.

**Final answer:**  $\text{Ag}^+$  (as  $[\text{Ag}(\text{NH}_3)_2]^+$ ) is a stronger oxidising agent than  $\text{Cu}^{2+}$ , since it can oxidise even the less reactive aromatic aldehyde (benzaldehyde), which fails to react with  $\text{Cu}^{2+}$  at all.

### Q7.18: Balance the following redox reactions by the ion-electron method

(i)  $\text{MnO}_4^- + \text{I}^- \rightarrow \text{MnO}_2 + \text{I}_2$  (basic medium). Mn:  $+7 \rightarrow +4$  (gain  $3e^-$ ); I:  $-1 \rightarrow 0$  (lose  $1e^-$  per I,  $2e^-$  per  $\text{I}_2$ ). Reduction half:  $\text{MnO}_4^- + 2\text{H}_2\text{O} + 3e^- \rightarrow \text{MnO}_2 + 4\text{OH}^-$ . Oxidation half:  $2\text{I}^- \rightarrow \text{I}_2 + 2e^-$ . Equalising electrons ( $\times 2$  and  $\times 3$ ) and adding:

(ii)  $\text{MnO}_4^- + \text{SO}_2 \rightarrow \text{Mn}^{2+} + \text{HSO}_4^-$  (acidic medium). Mn:  $+7 \rightarrow +2$  (gain  $5e^-$ ); S:  $+4 \rightarrow +6$  (lose  $2e^-$ ). Reduction half:  $\text{MnO}_4^- + 8\text{H}^+ + 5e^- \rightarrow \text{Mn}^{2+} + 4\text{H}_2\text{O}$ . Oxidation half:  $\text{SO}_2 + 2\text{H}_2\text{O} \rightarrow \text{HSO}_4^- + 3\text{H}^+ + 2e^-$ . Equalising electrons ( $\times 2$  and  $\times 5$ ) and adding, then cancelling common  $\text{H}_2\text{O}/\text{H}^+$ :

(iii)  $\text{H}_2\text{O}_2 + \text{Fe}^{2+} \rightarrow \text{Fe}^{3+} + \text{H}_2\text{O}$  (acidic medium). O:  $-1 \rightarrow -2$  (gain  $2e^-$  per  $\text{H}_2\text{O}_2$ ); Fe:  $+2 \rightarrow +3$  (lose  $1e^-$ ). Reduction half:  $\text{H}_2\text{O}_2 + 2\text{H}^+ + 2e^- \rightarrow 2\text{H}_2\text{O}$ . Oxidation half:  $2\text{Fe}^{2+} \rightarrow 2\text{Fe}^{3+} + 2e^-$ . Adding directly:

(iv)  $\text{Cr}_2\text{O}_7^{2-} + \text{SO}_2 \rightarrow \text{Cr}^{3+} + \text{SO}_4^{2-}$  (acidic medium). Cr:  $+6 \rightarrow +3$  per Cr (gain  $3e^-$  each,  $6e^-$  total); S:  $+4 \rightarrow +6$  (lose  $2e^-$ ). Reduction half:  $\text{Cr}_2\text{O}_7^{2-} + 14\text{H}^+ + 6e^- \rightarrow 2\text{Cr}^{3+} + 7\text{H}_2\text{O}$ . Oxidation half:  $\text{SO}_2 + 2\text{H}_2\text{O} \rightarrow \text{SO}_4^{2-} + 4\text{H}^+ + 2e^-$ . Equalising electrons ( $\times 1$  and  $\times 3$ ) and simplifying:

**Final answer:** The four balanced equations are as boxed above, each verified atom-by-atom and charge-by-charge using the ion-electron (half-reaction) method.

### Q7.19: Balance in basic medium by both methods; identify oxidising and reducing agents

(a)  $\text{P}_4(\text{s}) + \text{OH}^-(\text{aq}) \rightarrow \text{PH}_3(\text{g}) + \text{H}_2\text{PO}_2^-(\text{aq})$ . This is a disproportionation of  $\text{P}_4$  (oxidation state 0): one P is reduced to  $-3$  (in  $\text{PH}_3$ , gaining  $3e^-$ ) and another P is oxidised to  $+1$  (in  $\text{H}_2\text{PO}_2^-$ , losing  $1e^-$ ). Balancing the two half-reactions and combining in a 1:3 ratio of reduced to oxidised phosphorus gives, after simplification:

(checked: P 4=4, O 6=6, H 9=9, charge  $-3=-3$ ). Since  $\text{P}_4$  is simultaneously oxidised and reduced, it is both the oxidising agent and the reducing agent.

(b)  $\text{N}_2\text{H}_4(\text{l}) + \text{ClO}_3^-(\text{aq}) \rightarrow \text{NO}(\text{g}) + \text{Cl}^-(\text{aq})$ . N:  $-2 \rightarrow +2$  per N (oxidation,  $4e^-$  per N,  $8e^-$  per  $\text{N}_2\text{H}_4$ ); Cl:  $+5 \rightarrow -1$  (reduction,  $6e^-$ ). Oxidation half:  $\text{N}_2\text{H}_4 + 8\text{OH}^- \rightarrow 2\text{NO} + 6\text{H}_2\text{O} + 8e^-$ . Reduction half:  $\text{ClO}_3^- + 3\text{H}_2\text{O} + 6e^- \rightarrow \text{Cl}^- + 6\text{OH}^-$ . Equalising electrons (LCM 24:  $\times 3$  and  $\times 4$ ) and simplifying:

Oxidising agent =  $\text{ClO}_3^-$ ; reducing agent =  $\text{N}_2\text{H}_4$ .

(c)  $\text{Cl}_2\text{O}_7(\text{g}) + \text{H}_2\text{O}_2(\text{aq}) \rightarrow \text{ClO}_2^-(\text{aq}) + \text{O}_2(\text{g}) + \text{H}^+$ . Cl:  $+7 \rightarrow +3$  (reduction,  $4e^-$  per Cl,  $8e^-$  per  $\text{Cl}_2\text{O}_7$ ); O (peroxide):  $-1 \rightarrow 0$  (oxidation,  $2e^-$  per  $\text{H}_2\text{O}_2$ ). Reduction half:  $\text{Cl}_2\text{O}_7 + 6\text{H}^+ + 8e^- \rightarrow 2\text{ClO}_2^- + 3\text{H}_2\text{O}$ . Oxidation half:  $\text{H}_2\text{O}_2 \rightarrow \text{O}_2 + 2\text{H}^+ + 2e^-$ . Equalising electrons ( $\times 1$  and  $\times 4$ ) and simplifying:

Oxidising agent =  $\text{Cl}_2\text{O}_7$ ; reducing agent =  $\text{H}_2\text{O}_2$ .

**Final answer:** (a)  $\text{P}_4 + 3\text{OH}^- + 3\text{H}_2\text{O} \rightarrow \text{PH}_3 + 3\text{H}_2\text{PO}_2^-$  ( $\text{P}_4$  is both oxidant and reductant); (b)  $3\text{N}_2\text{H}_4 + 4\text{ClO}_3^- \rightarrow 6\text{NO} + 4\text{Cl}^- + 6\text{H}_2\text{O}$  (oxidant:  $\text{ClO}_3^-$ , reductant:  $\text{N}_2\text{H}_4$ ); (c)  $\text{Cl}_2\text{O}_7 + 4\text{H}_2\text{O}_2 \rightarrow 2\text{ClO}_2^- + 4\text{O}_2 + 3\text{H}_2\text{O} + 2\text{H}^+$  (oxidant:  $\text{Cl}_2\text{O}_7$ , reductant:  $\text{H}_2\text{O}_2$ ).

### Q7.20: What information can you draw from the cyanogen disproportionation reaction?

$(\text{CN})_2(\text{g}) + 2\text{OH}^-(\text{aq}) \rightarrow \text{CN}^-(\text{aq}) + \text{CNO}^-(\text{aq}) + \text{H}_2\text{O}(\text{l})$ . Assigning oxidation numbers (N =  $-3$  throughout, O =  $-2$ ): in cyanogen,  $(\text{CN})_2$ , carbon is at  $+3$  (average); in the product cyanide ion,  $\text{CN}^-$ , carbon is at  $+2$ ; in the product cyanate ion,  $\text{CNO}^-$ , carbon is at  $+4$ . So carbon splits from  $+3$  into  $+2$  (reduced) and  $+4$  (oxidised) — a disproportionation. This is exactly analogous to the disproportionation of a halogen in alkali, e.g.,  $\text{Cl}_2 + 2\text{OH}^- \rightarrow \text{Cl}^- + \text{OCl}^- + \text{H}_2\text{O}$ , which is why  $(\text{CN})_2$  is classed as a pseudohalogen.

**Final answer:** The reaction shows that  $(\text{CN})_2$  undergoes disproportionation (carbon splits from +3 into +2 in  $\text{CN}^-$  and +4 in  $\text{CNO}^-$ ) in exactly the same pattern as a halogen reacting with alkali, confirming cyanogen's classification as a "pseudohalogen."

#### Q7.21: Balanced equation for $\text{Mn}^{3+}$ disproportionation

---

$\text{Mn}^{3+}$  is unstable in solution and disproportionates to  $\text{Mn}^{2+}$  and  $\text{MnO}_2$ . One  $\text{Mn}^{3+}$  is reduced to  $\text{Mn}^{2+}$  (gains  $1e^-$ ); another  $\text{Mn}^{3+}$  is oxidised to  $\text{Mn}^{4+}$  as  $\text{MnO}_2$  (loses  $1e^-$ , and needs O supplied by water, releasing  $\text{H}^+$ ). Combining 1:1 and supplying oxygen/hydrogen via water:

Check: Mn 2=2; O 2=2; H 4=4; charge LHS +6, RHS (+2) + (+4 from  $4\text{H}^+$ ) = +6. Balanced.

**Final answer:**  $2\text{Mn}^{3+}(\text{aq}) + 2\text{H}_2\text{O}(\text{l}) \rightarrow \text{Mn}^{2+}(\text{aq}) + \text{MnO}_2(\text{s}) + 4\text{H}^+(\text{aq})$ .

#### Q7.22: Oxidation-state behaviour of Cs, Ne, I and F

---

- (a) Element showing only a negative oxidation state: **F** (the most electronegative element of all, never found in a positive oxidation state).  
(b) Element showing only a positive oxidation state: **Cs** (a highly electropositive alkali metal, essentially always +1).  
(c) Element showing both positive and negative oxidation states: **I** (iodine is -1 in iodides, but can be +1, +3, +5 or +7 in oxoacids, oxides and interhalogen compounds).  
(d) Element showing neither a positive nor a negative oxidation state (stays at 0): **Ne** (a noble gas that forms essentially no stable compounds).

**Final answer:** F = only negative; Cs = only positive; I = both positive and negative; Ne = neither (stays at 0).

#### Q7.23: Balanced equation for removing excess chlorine from drinking water with $\text{SO}_2$

---

$\text{Cl}_2$  is reduced ( $0 \rightarrow -1$ ) and  $\text{SO}_2$  is oxidised ( $+4 \rightarrow +6$ , forming sulphate/sulphuric acid), consuming water:

Check: Cl 2=2; S 1=1; O 4=4; H 4=4. Balanced.

**Final answer:**  $\text{Cl}_2(\text{aq}) + \text{SO}_2(\text{g}) + 2\text{H}_2\text{O}(\text{l}) \rightarrow 2\text{HCl}(\text{aq}) + \text{H}_2\text{SO}_4(\text{aq})$ .

#### Q7.24: Non-metals and metals that show disproportionation

---

- (a) Possible non-metals: elements with several accessible intermediate oxidation states, such as **Cl, Br, I** (halogens: e.g.  $\text{Cl}_2 + 2\text{OH}^- \rightarrow \text{Cl}^- + \text{OCl}^- + \text{H}_2\text{O}$ ), **P** (e.g.  $\text{P}_4 \rightarrow \text{PH}_3 + \text{H}_2\text{PO}_2^-$ , as in Q7.19a), and **S** (e.g.  $\text{S}_8$  in hot alkali giving sulfide- and thiosulfate-type products).  
(b) Three metals: **Cu** ( $2\text{Cu}^+ \rightarrow \text{Cu}^{2+} + \text{Cu}$ , since  $\text{Cu}^+$  is unstable in aqueous solution), **Au** ( $3\text{Au}^+ \rightarrow \text{Au}^{3+} + 2\text{Au}$ ), and **Mn** ( $\text{Mn}^{3+} \rightarrow \text{Mn}^{2+} + \text{MnO}_2$ , as in Q7.21).

**Final answer:** Non-metals: Cl, Br, I, P, S; Metals: Cu, Au, Mn, each chosen because the element has an intermediate oxidation state that can simultaneously rise and fall.

#### Q7.25: Maximum mass of NO from the Ostwald process (limiting-reagent calculation)

---

$4\text{NH}_3(\text{g}) + 5\text{O}_2(\text{g}) \rightarrow 4\text{NO}(\text{g}) + 6\text{H}_2\text{O}(\text{g})$ . Molar mass  $\text{NH}_3 = 17 \text{ g/mol}$ ;  $\text{O}_2 = 32 \text{ g/mol}$ ;  $\text{NO} = 30 \text{ g/mol}$ .  
Moles of  $\text{NH}_3 = 10.00/17 = 0.588 \text{ mol}$ . Moles of  $\text{O}_2 = 20.00/32 = 0.625 \text{ mol}$ .

Required  $\text{O}_2$  for all the  $\text{NH}_3$  (ratio  $\text{NH}_3:\text{O}_2 = 4:5$ )  $= 0.588 \times (5/4) = 0.735 \text{ mol}$ , but only  $0.625 \text{ mol}$   $\text{O}_2$  is available  $\rightarrow \text{O}_2$  is the limiting reagent.

Moles of  $\text{NO}$  formed  $= \text{moles } \text{O}_2 \text{ used} \times (4/5) = 0.625 \times 0.8 = 0.500 \text{ mol}$ .

Mass of  $\text{NO} = 0.500 \text{ mol} \times 30 \text{ g/mol} = 15.0 \text{ g}$ .

**Final answer: 15.0 g of NO is the maximum obtainable, since O<sub>2</sub> (not NH<sub>3</sub>) is the limiting reagent.**

### Q7.26: Feasibility of reactions from standard electrode potentials

Using standard reduction potentials:  $\text{Fe}^{3+}/\text{Fe}^{2+} = +0.77 \text{ V}$ ;  $\text{I}_2/\text{I}^- = +0.54 \text{ V}$ ;  $\text{Ag}^+/\text{Ag} = +0.80 \text{ V}$ ;  $\text{Cu}^{2+}/\text{Cu} = +0.34 \text{ V}$ ;  $\text{Br}_2/\text{Br}^- = +1.09 \text{ V}$ . A reaction is spontaneous when the species with the higher (more positive) reduction potential is reduced by the species with the lower one.

- (a)  $\text{Fe}^{3+} + \text{I}^-$ :  $0.77 \text{ V} > 0.54 \text{ V}$ , so  $\text{Fe}^{3+}$  can oxidise  $\text{I}^-$ . **Feasible:**  $2\text{Fe}^{3+} + 2\text{I}^- \rightarrow 2\text{Fe}^{2+} + \text{I}_2$ .  
(b)  $\text{Ag}^+$  and  $\text{Cu}$ :  $0.80 \text{ V} > 0.34 \text{ V}$ , so  $\text{Ag}^+$  can oxidise  $\text{Cu}$ . **Feasible:**  $2\text{Ag}^+ + \text{Cu} \rightarrow 2\text{Ag} + \text{Cu}^{2+}$ .  
(c)  $\text{Fe}^{3+}$  and  $\text{Cu}$ :  $0.77 \text{ V} > 0.34 \text{ V}$ , so  $\text{Fe}^{3+}$  can oxidise  $\text{Cu}$ . **Feasible:**  $2\text{Fe}^{3+} + \text{Cu} \rightarrow 2\text{Fe}^{2+} + \text{Cu}^{2+}$ .  
(d)  $\text{Ag}$  and  $\text{Fe}^{3+}$ : this would require  $0.77 \text{ V} > 0.80 \text{ V}$ , which is false ( $E^\circ_{\text{cell}} = 0.77 - 0.80 = -0.03 \text{ V}$ ). **Not feasible.**  
(e)  $\text{Br}_2$  and  $\text{Fe}^{2+}$ :  $1.09 \text{ V} > 0.77 \text{ V}$ , so  $\text{Br}_2$  can oxidise  $\text{Fe}^{2+}$ . **Feasible:**  $2\text{Fe}^{2+} + \text{Br}_2 \rightarrow 2\text{Fe}^{3+} + 2\text{Br}^-$  ( $E^\circ_{\text{cell}} = +0.32 \text{ V}$ ).

**Final answer: Feasible: (a), (b), (c) and (e); Not feasible: (d), since Ag<sup>+</sup>/Ag (0.80 V) has a higher reduction potential than Fe<sup>3+</sup>/Fe<sup>2+</sup> (0.77 V), so silver metal cannot reduce Fe<sup>3+</sup>.**

### Q7.27: Products of electrolysis

- (i) Aqueous  $\text{AgNO}_3$  with silver electrodes: silver dissolves from the anode and deposits on the cathode, net effect being transfer of silver metal from anode to cathode with no change in solution concentration.  
(ii) Aqueous  $\text{AgNO}_3$  with platinum (inert) electrodes:  $\text{Ag}^+$  is reduced at the cathode, depositing silver metal; at the anode, water is oxidised instead of  $\text{NO}_3^-$ :  $2\text{H}_2\text{O} \rightarrow \text{O}_2 + 4\text{H}^+ + 4\text{e}^-$ , releasing  $\text{O}_2$  gas.  
(iii) Dilute  $\text{H}_2\text{SO}_4$  with platinum electrodes: essentially electrolysis of water, giving  $\text{H}_2$  gas at the cathode and  $\text{O}_2$  gas at the anode, in a 2:1 volume ratio.  
(iv) Aqueous  $\text{CuCl}_2$  with platinum electrodes:  $\text{Cu}^{2+}$  is reduced and deposited as copper metal at the cathode;  $\text{Cl}^-$  is oxidised at the anode to  $\text{Cl}_2$  gas.

**Final answer: (i) Ag transferred anode  $\rightarrow$  cathode, solution unchanged; (ii) Ag deposited at cathode,  $\text{O}_2$  evolved at anode; (iii)  $\text{H}_2$  at cathode,  $\text{O}_2$  at anode (2:1 by volume); (iv) Cu deposited at cathode,  $\text{Cl}_2$  gas evolved at anode.**

### Q7.28: Arranging Al, Cu, Fe, Mg and Zn by displacement order

Using standard reduction potentials (more negative = more easily oxidised = more reactive):  $\text{Mg}^{2+}/\text{Mg} \approx -2.36 \text{ V}$ ,  $\text{Al}^{3+}/\text{Al} \approx -1.66 \text{ V}$ ,  $\text{Zn}^{2+}/\text{Zn} \approx -0.76 \text{ V}$ ,  $\text{Fe}^{2+}/\text{Fe} \approx -0.44 \text{ V}$ ,  $\text{Cu}^{2+}/\text{Cu} = +0.34 \text{ V}$ .

**Final answer:  $\text{Mg} > \text{Al} > \text{Zn} > \text{Fe} > \text{Cu}$  (most reactive/best displacer first) — each metal in this list displaces every metal to its right from solutions of their salts.**

### Q7.29: Increasing order of reducing power from given electrode potentials

Given:  $K^+/K = -2.93$  V,  $Ag^+/Ag = +0.80$  V,  $Hg^{2+}/Hg = +0.79$  V,  $Mg^{2+}/Mg = -2.37$  V,  $Cr^{3+}/Cr = -0.74$  V.  
Reducing power increases as the standard reduction potential becomes more negative.

**Final answer:**  $Ag < Hg < Cr < Mg < K$  (increasing reducing power), following directly from arranging the given  $E^\circ$  values from most positive to most negative.

### Q7.30: Depicting the Zn/Ag galvanic cell

$Zn(s) + 2Ag^+(aq) \rightarrow Zn^{2+}(aq) + 2Ag(s)$ . Cell representation:  $Zn(s) | Zn^{2+}(aq) || Ag^+(aq) | Ag(s)$ .

- (i) The zinc electrode is the **anode** (where oxidation occurs), and in a galvanic cell the anode is the **negatively charged** electrode.
- (ii) Current carriers: inside the cell, ions carry the current through the electrolyte; in the external circuit, electrons flowing from zinc to silver carry the current.
- (iii) Electrode reactions: anode (Zn):  $Zn(s) \rightarrow Zn^{2+}(aq) + 2e^-$  (oxidation). Cathode (Ag):  $2Ag^+(aq) + 2e^- \rightarrow 2Ag(s)$  (reduction).

**Final answer:** Zinc electrode = negative (anode); current is carried by ions in solution and electrons in the external wire; anode reaction  $Zn \rightarrow Zn^{2+} + 2e^-$ , cathode reaction  $2Ag^+ + 2e^- \rightarrow 2Ag$ .

## Class 11 Chemistry Chapter 7 – Notes and Extra Questions

Beyond these thirty exercise questions, students preparing for school tests and competitive exams should revise the oxidation-number rules, the four types of redox reactions (combination, decomposition, displacement and disproportionation), both balancing methods (oxidation-number and ion-electron), and the standard electrode potential series, since these form the conceptual backbone of electrochemistry (Class 12) and inorganic chemistry that follows this chapter. Practising extra numericals on limiting-reagent redox stoichiometry and half-reaction balancing in both acidic and basic media is the best way to build speed for board and entrance exams.
